

MULTIVARIATE SHAPE ANALYSIS

By I. L. DRYDEN and K.V.MARDIA
University of Leeds, U. K.

SUMMARY. This paper reviews the present state of the art in shape analysis, as well as introducing a few new ideas. The paper begins with a definition of size and then various coordinate systems for shape are considered - the QR decomposition and Bookstein shape variables in particular. Concepts of distance are reviewed including the Procrustes and Riemannian distances. Gaussian models for configurations are then considered, including perturbation models and principal components models. These models, offset in the size and shape or shape spaces, could then be used for size and shape analysis. However, this approach is complicated and we outline approximations based on tangent spaces - the preshape tangent space and the Procrustes tangent space. Standard multivariate analysis can then be performed, for example Hotelling's T^2 test and principal components analysis. We also consider a distribution free approach. Finally, we illustrate the methods with a practical 3D application in biology.

1. INTRODUCTION

Shape analysis is an area of study arising from a wide variety of applications, including in archaeology, biology, chemistry, geography, image analysis and medicine. It is only within the last decade that satisfactory techniques have emerged for landmark data.

The word "shape" is very commonly used in everyday language, usually referring to the appearance of an object. The definition of shape that we consider is intuitive: **shape** is all the geometrical information that remains when location, scale and rotational effects are removed (D.G. Kendall (1984)). So, an object's shape is invariant under the similarity transformations of translation, scaling and rotation. For example, the shape of a human skull consists of all the geometrical properties of the skull that are unchanged when it is translated, rescaled or rotated in an arbitrary coordinate system, i.e., it is invariant under 'pose'. Two objects have the same shape if we can translate, rescale and rotate them to each other so that they match exactly, i.e., if the objects are similar.

The classical way to analyse shape is to locate a finite number of landmarks on each specimen. A **landmark** is a point of correspondence on each object that matches between and within populations. There are three types of landmarks in most applications: biological, mathematical and pseudo-landmarks.

A **biological landmark** is a point assigned by an expert that corresponds in some biologically meaningful way, eg. the pupil of an eye or the meeting of two sutures on a skull. Biological landmarks designate parts of an organism that correspond in terms of biological function and these parts are called homologous (Jardine and Jardine (1967)). **Mathematical landmarks** are points located on an object according to some geometrical property of the figure, eg.

at a point of high curvature or at an extreme point. The use of mathematical landmarks is particularly useful in automatic recognition and analysis, and for example an algorithm for locating landmarks semi-automatically on the outline of a mouse vertebra as described in Mardia (1989). **Pseudo-landmarks** are points constructed in between biological or mathematical landmarks. For example, if many equally spaced points are taken on the outline of a bone between biological landmarks then these are classed as pseudo-landmarks.

Our notation will be that there are k landmarks in m dimensions, where in practice we usually have $k \geq 3$ and $m = 2$ or $m = 3$. Point configurations can be labelled or unlabelled. Labelled configurations have each landmark assigned a name or number and the landmark with say label 1 on one specimen corresponds in some meaningful way with landmark 1 on another specimen. The methods considered in this paper are for labelled configurations.

The spirit of this work follows Mahalanobis in being motivated by practical examples. It is an honour to contribute an article in this volume on this new and challenging area of shape analysis.

2. SIZE AND SHAPE COORDINATES

2.1 Size. Before considering shape we should define what we mean by size, so that it can be removed from a configuration. We consider precisely the same notion of size as that defined by Mosimann (1970). Consider p positive length measurements $l = (l_1, \dots, l_p)'$, $p \geq 2$, which are distances between landmarks or pseudo-landmarks. A standard size variable is any real valued function $g(l)$ such that $g(al) = ag(l)$ for positive a, l_1, \dots, l_p . If X is a $k \times m$ matrix of k landmarks in m dimensions, then a suitable size measurement could be the centroid size

$$S(X) = \|CX\| = \sqrt{\sum_{i=1}^k \sum_{j=1}^m (X_{ij} - \bar{X}_j)^2} \tag{1}$$

where $\bar{X}_j = \frac{1}{k} \sum_{i=1}^k X_{ij}$,

$$C = I_k - \frac{1}{k} \mathbf{1}_k \mathbf{1}'_k,$$

and $\|X\| = \text{tr}(X'X)^{\frac{1}{2}}$ is the Euclidean norm, I_k is the $k \times k$ identity matrix and $\mathbf{1}_k$ is the $k \times 1$ vector of ones. Note that C is the centering matrix. The centroid size is the most commonly used in geometrical shape analysis (e.g., Bookstein (1986), Kendall (1984), (1989), Goodall (1991), Dryden and Mardia (1992)). Geometrically $S(X)$ is the square root of the sum of squared Euclidean distances from each landmark to the centroid.

An alternative could be to use the 'baseline size', i.e. the length between landmarks 1 and 2 (Bookstein, (1986)).

$$D = \|(X)_2 - (X)_1\| \tag{2}$$

where $(X)_i$ is the i th row of X , $i = 1, \dots, k$. Other alternative size measures include the square root of area for planar configurations or the cube root of volume for 3D configurations.

Mosimann (1970) defines the shape vector to be $l/g(l)$ and this differs fundamentally from our approach to shape. In our formalism shape is not constructed from positive lengths but directly from the Cartesian coordinates after removing the similarity transformations.

2.2 Shape : QR decomposition. Let us consider k landmarks in m dimensions for general m with $k > m$. Given a $k \times m$ matrix of landmark coordinates X , location can be removed by premultiplying X by a suitable matrix H , where H is the Helmert matrix without the first row, defined by having its first row of elements equal to $1/\sqrt{k}$ and the remaining rows are orthogonal to the first row. Explicitly, the j th row of H is given by,

$$(d_j, \dots, d_j, -jd_j, 0, \dots, 0),$$

where $d_j = -\{j(j+1)\}^{-\frac{1}{2}}$ is repeated j times and $j = 1, \dots, k-1$. A QR decomposition of Y then leads to

$$Y = T\Gamma, \quad \Gamma \in SO(m),$$

where the $(k-1) \times m$ lower triangular matrix T contains size-&-shape coordinates.

Note that T is invariant under the original location and rotation of the configuration. The matrix T has zero entries above the leading diagonal and therefore $(k-1)m - m(m-1)/2$ size-&-shape coordinates.

To obtain the shape coordinates we divide by the scale : $W = T/\|T\|$ and so there are $(k-1-m)m + (m-1)(m-2)/2$ shape coordinates. Note that $S(X) = \|T\| = \|Y\|$ is the centroid size. This coordinate system was introduced in Goodall and Mardia (1992).

A slight variant of this coordinate system includes using a different translation matrix from H such as B where the j th row of B is $(-1, 1, 0, \dots, 0)$ if $j = 1$ and

$$\left(-\frac{1}{2}, \frac{1}{2}, 0, \dots, 0, 1, 0, \dots, 0\right) \quad 1 < j \leq k-1,$$

and the 1 is in the $(j+1)$ th column (see Dryden and Mardia (1991)). Another alternative is to use a different scale such as the $(1, 1)$ th element of T . Note that we could have removed the similarity transformations in a different order. After translating we could have rescaled to give,

$$Z = HX/\|HX\|$$

$$\hat{\mu} = \frac{1}{l} \sum_{i=1}^l X_i^p, \quad (8)$$

An alternative approach could be to use model based estimation.

3. SHAPE MODELS

3.1 *Perturbation models* Goodall and Mardia (1993) and Dryden and Mardia (1991, 1992) consider the models

$$x = \text{vec}(X) = \mu + \varepsilon \quad (9)$$

where $\varepsilon \sim N(0, \Sigma)$. For $m = 2$ Dryden and Mardia (1991, 1992) have given the joint marginal size-and-shape and marginal shape distributions, by integrating out the similarity transformations. The distributions are particularly simple if Σ is of complex normal form. We consider the particular case here when $k = 3$ and $m = 2$ and $\Sigma = \sigma^2 I$. The joint p.d.f. of Bookstein's shape variables (U, V) is given by (Mardia and Dryden, 1989a,b),

$$\frac{1}{3\pi(\frac{1}{2} + \frac{2}{3}u^2 + \frac{2}{3}v^2)^2} \{1 + \kappa(1 + \cos 2\rho)\} \exp\{-\kappa(1 - \cos 2\rho)\},$$

where

$$\kappa = S^2(\mu) / (4\sigma^2),$$

is a concentration parameter and ρ is the Riemannian distance between the observed shape (u, v) and the population shape (θ, ϕ) of μ , given in equation (6). This has been referred to in the literature as the 'Mardia-Dryden' distribution (Kendall, (1991)).

For $m > 2$ Goodall and Mardia (1993) have investigated size and shape distributions for factored covariances, although the densities are not explicitly known if μ is of full rank.

These models can be used for large sample likelihood based inference and implementation is fairly straightforward for $m = 2$ providing simple covariance structures are adopted. Inference for general Σ or $m \geq 3$ is complicated.

Goodall (1991) considers an alternative approach with factor covariance structures. The Procrustes approach that he considers (see brief details in Section 2.4) involves estimation of the similarity transformations rather than integrating them out.

Kent (1994) approaches modelling through the complex Bingham distribution on the preshape sphere with p.d.f. given by,

$$f(z) = c(A) \exp(\text{tr} z z^{\bar{j}} A), \quad (10)$$

and this fits in well with the Procrustes approach. It is suitable for modelling shape because the distribution is rotationally invariant, $f(e^{i\theta}z) = f(z)$.

3.2 *Principal components models.* Cootes et al.(1992) consider the point distribution model which is a principal component model for shape. Let $x = \text{vec}(X)$; then we formulate their principal component model for configurations as

$$x = \mu + \sum_{i=1}^p y_i \gamma_i + \varepsilon, \tag{11}$$

where

$$y_i \sim N(0, \lambda_i), \quad \varepsilon \sim N(0, \sigma^2),$$

independently and

$$\mu' \gamma_i = 0, \quad \gamma_i' \gamma_i = 1, \gamma_i' \gamma_j = 0, \quad (i \neq j),$$

and $\lambda_1 \geq \lambda_2 \dots \geq \lambda_p$. Here $p \leq k$ and p is preferably taken to be quite small.

Note that, this approach allows us to give a model for flexible varying shapes, with often interpretable principal components. The interpretation of each component can be seen by varying y_i in equation (11) while keeping the other $y_j, j \neq i$, equal to zero. In practice the population parameters must be estimated from a random sample. Let $\hat{\mu}$ and $\hat{\gamma}_i$ be the estimates of μ and γ_i . Then $x = \hat{\mu} + y_i \hat{\gamma}_i$ for different y_i (but fixed i) captures different aspects of shape variation, e.g. relative length, relative width, bending, movement of a subset of landmarks relative to the rest and so on. A practical example will be considered in Section 6.

Of course the principal component model is a special case of the model of equation (9) and the covariance matrix is

$$\Sigma = \sigma^2 I_{mk} + \sum_{i=1}^p \lambda_i \gamma_i \gamma_i' \tag{12}$$

Hence, details of the size and shape distributions are available for $m = 2$ in Dryden and Mardia (1991, 1992) and what is known for $m \geq 3$ is given in Goodall and Mardia (1993). Thereafter, inference for large samples could proceed using likelihood based methods.

However, this is complicated in general (particularly for $m \geq 3$) and so we consider various approximations for the situation where the variability in the dataset is small.

4. APPROXIMATIONS

4.1 *Local shape coordinates : tangent spaces.* If variations in a dataset are small then one could consider a local coordinate system. For example one

as possible to the pole. If the transformed coordinates are X^P , the Procrustes tangent coordinates are given by,

$$X^P - \gamma$$

In practice the pole γ is chosen to be the Procrustes mean shape $\hat{\mu}$ given by (8).

4.2 Inference in tangent spaces. Kent (1994) suggest the use of the tangent space coordinates if the data are concentrated and then performs standard multivariate analysis (e.g. Mardia, Kent and Bibby, 1979) in this linear space. This is an approximation to inference using the general model of equation (9). Kent's procedure is easily extended to $m \geq 3$ using the above tangentspace coordinates of equation (15). For example consider the case where we wish to test for mean shape difference between two independent populations. Given independent random samples $X_1, \dots, X_{n_1}, Y_1, \dots, Y_{n_2}$ we consider the pole as the overall Procrustes mean obtained by GPA on all $n_1 + n_2$ observations. A test for differences in covariances is carried out (e.g., Box's M test). If there is not a significant difference in the covariances then a Hotelling's T^2 test is carried out on the tangent space coordinates. Note that the space is singular and so a convenient approach is to retain $(k-1)m - m(m-1)/2 - 1$ of the coordinates in the analysis.

4.3 PCA in tangent spaces. In order to estimate the parameters of the principal components model with covariance matrix (12) instead of exact marginal MLE mentioned in Section 3.2 we could consider the Procrustes tangent space, providing variations are small.

Given l independent configurations X_1, \dots, X_l , estimates of the above parameters can be obtained by first registering the shapes by GPA and then performing a principal component analysis. Cootes et al. (1992) use a type of weighted Procrustes analysis to obtain registered figures X_1^P, \dots, X_l^P . The estimate of μ is taken to be the Procrustes mean of equation (8) and $\hat{\gamma}_i, i = 1, \dots, \min(l, k)$ are the eigenvectors of

$$\frac{1}{l} \sum_{i=1}^l (\text{vec}(X_i) - \hat{\mu})(\text{vec}(X_i) - \hat{\mu})'$$

with corresponding decreasing eigenvalues $\hat{\lambda}_i$. Given a training set of data this approach allows us to give a model for flexible varying shapes, as described in Section 3.2. Note that the Cootes et al (1992) approach is effectively PCA in the Procrustes tangent space.

Alternatively Kent (1994) has suggested PCA in the tangent space defined in equation (10), which is simply extended here to the situation of equation (15) for general m . This involves a model specified in the tangent space coordinates

Fig. 1. An 'artists's impression of a skull, indicating the rough position of the landmarks, in the a) x - y , b) x - z and c) y - z projections. The landmarks (• if on show, × if hidden from view) are named in the text.

Fig. 2. The 3D male skull data superimposed by general Procrustes analysis. The three figures show projections into the a) x - y , b) x - z and c) y - z planes.

Fig. 3. The female skull data superimposed by general Procrustes analysis. The three figures show projections into the a) x - y , b) x - z and c) y - z planes. The same scale is used in Fig. 2.

Fig. 4. The male (●) and female (+) mean shapes obtained by GPA and scaled to unit size, projected into the x - y (above left), x - z (below left), y - z (above right) planes.

Fig. 5. The first principal component for the males. The figures are projections of the mean shape $\hat{\mu}(\bullet)$ with displacement vectors from ± 3 standard deviations from the mean (details in the text). The vectors show $z_{\alpha/2}$ in equation (18) varying from 0 to 3 (---) and from -3 to 0 (—), and they are magnified 3 times for ease of visualization.

Fig. 6. The first principal component for the males. The figures are a) x - y , b) x - z and c) y - z projections of the figures evaluated along the first principal component. The plots show figures evaluated from equation (18) with $z_{\alpha/2} = -3$ (far left), -2 , -1 , 0 , 1 , 2 , 3 (far right).
